Land Subsidence of Java North Coast Observed by SAR Interferometry

Integrating Ground Penetrating Radar, Induced Polarization and Aerial Photograph to Analyze Land Subsidence in Borehole Mining Operation Area: A Case Study from South Bangka Island

On-Line Course

*Model how land subsidence affects flooding*

**Requirements**
ArcGIS Pro (get a free trial)
ArcGIS Spatial Analyst extension

**Lesson Plan**

**Prepare data for analysis**
Create the initial elevation datasets that will be used during analysis.
15 minutes

**Model land subsidence**
Calculate elevation by 2050 due to land subsidence.
10 minutes

**Determine damage caused by flooding**
Find areas susceptible to flooding and estimate potential damage to buildings.
25 minutes

**Compare flooding scenarios**
Observe how flooding may change by 2050.
10 minutes
New Literature

**Europe**

**Great Britain, India**

Tropical peat subsidence rates are related to decadal LULC changes: Insights from InSAR analysis,

Abstract: Peatlands in Indonesia are subject to subsidence in recent years, resulting in significant soil organic carbon loss. Their degradation is responsible for several environmental issues; however, understanding the causes of peatland subsidence is of prime concern for implementing mitigation measures. Here, we employed time-series Small BAseline Subset (SBAS) Interferometric Synthetic Aperture Radar (InSAR) using ALOS PALSAR-2 images to assess the relationship between subsidence rates and land use/land cover (LULC) change (including drainage periods) derived from decadal Landsat data (1972–2019). Overall, the study area subsided with a mean rate of $-2.646 \pm 1.839$ cm/year in 2018–2019. The subsidence rates slowed over time, with significant subsidence decreases in peatlands after being drained for 9 years. We found that the long-time persistence of vegetated areas leads to subsidence deceleration. The relatively lower subsidence rates are in areas that changed to rubber/mixed plantations. Further, the potential of subsidence prediction was assessed using Random Forest (RF) regression based on LULC change, distance from peat edge, and elevation. With an R2 of 0.532 (RMSE = 0.594 cm/year), this machine learning method potentially enlarges the spatial coverage of InSAR method for the higher frequency SAR data (such as Sentinel-1) that mainly have limited coverage due to decorrelation in vegetated areas. According to feature importance in the RF model, the contribution of LULC change (including drainage period) to the subsidence model is comparable with distance from peat edge and elevation. Other uncertainties are from unexplained factors related to drainage and peat condition, which need to be accounted for as well. This work shows the significance of decadal LULC change analysis to supplement InSAR measurement in tropical peatland subsidence monitoring programs.

Abstract: The freshwater scarcity and sustainability of overexploited aquifers have been recognized as a big threat to global water security for human development. Consequently, much research has focused in the past on negative consequences of groundwater abstraction, but somewhat less has been documented about the impacts of adequate management practices to address water shortages. Here, using an integrated analysis of InSAR displacement data, groundwater, and geophysical modeling we show how combined management provisions and inter-basin water transfer project has affected the aquifer system in Taiyuan basin in North China. Following groundwater recovery, the alleviation of land subsidence was found with rates being reduced by up to ~70% in the period 2017–2020 with respect to the period 2007–2010. The increase in pore pressure caused by rising groundwater in Taiyuan city, north of the basin, turned four subsidence centers with rates exceeding 110 mm/yr in the 1980 to uplift centers with rates up to +25 mm/yr between 2017 and 2020. A simple linear elastic model for homogenous subsurface properties can explain InSAR-measured surface displacements well. In the central basin, we found a significant seasonal displacement with annual amplitude up to 43 mm (negative peak in autumn and positive peak in spring) related to the groundwater recharge and discharge due to agricultural pumping irrigation. Using cross-wavelet method, we showed a relatively short time lags (less than one month) between surface deformation and water level changes in the central basin, indicating the low-permeability clayey units have a limited influence in delaying the compaction of aquifer system. Quantifying the effects of adequate groundwater management measures and large-scale engineering approaches like inter-basin water transfer to recharge pumped aquifers provide insight for local governments and decision-makers to properly evaluate the impacts of their policy in recovering the sustainability and efficiency of aquifers in water-deficient basins.

Estimating future (next-month’s) spatial groundwater response from current regional pumping and precipitation rates, Journal of Hydrology, 2021, 127160, ISSN 0022-1694,

Abstract: The equilibrium of natural groundwater systems can be disrupted by excessive withdrawal. Accurate estimation of groundwater levels is needed to assess water-level fluctuations caused by groundwater withdrawal and seasonal distributions of precipitation. This study aims to estimate the next-month’s groundwater levels using monthly real-world data that includes rainfall, electricity-estimated pumping volumes, and current groundwater levels invoking time-dependent spatial regression. The new approach involves state-estimation and change-estimation methods, which will be evaluated to determine the optimal model based on its root mean square error values. The response of estimated future (next-month’s) groundwater levels within the alluvial fan in Changhua and Yunlin, Taiwan is based on monthly precipitation and pumping. This study yields a data-driven explanation of how water levels temporally and spatially respond to groundwater pumping and rainfall infiltration in different regions within the alluvial fan. Results indicate that the proximal fan yields the smallest response to decreased groundwater levels and subsequent increases in pumping. The effect of reducing groundwater levels is greater in the southern areas of the study site than in the northern areas. Water levels in the mid-fan and distal-fan in the southern area show a greater drawdown due to larger pumping volumes compared to the northern area.

Abstract: Longwall caving mining (LCM) can lead to many environmental problems that have drawn worldwide attention. A previous survey found that most scholars tend to analyze the two issues separately, that is, coal mining-induced subsidence and heavy metal pollution sources in the soil of the mining regions. Based on field monitoring as well as the collection and analysis of soil samples, a previous study estimated ground settlement and analyzed the surface subsidence law and spatial distribution characteristics of heavy metals in soils. Moreover, a geographic information system was combined with multivariate statistical analysis methods to analyze the heavy metal pollution sources
in soils. At the same time, the mechanism of heavy metal accumulation in the subsidence area was analyzed. The study found that the most active subsidence of settlement was 137.5m behind the workface and moved forward with the workface. LCM has already caused significant disturbance to the soils in the Hengyuan Mine. Moreover, the distribution pattern of eight heavy metals was consistent with the surface subsidence law. The sources of heavy metal pollution in the soils were also identified; namely, coal mining-induced subsidence (64.1%) and mixed transportation and wind-mediated spread (35.9%), offering a reinterpretation of the LCM’s footprint.

Ahmedabad: ‘Walled City least affected by sinking of land’
Indonesia,

A man fishes in water inundating the area around an abandoned building due to the rising sea levels and land subsidence in Sidogemah, Central Java, Indonesia, Monday, Nov. 8, 2021. World leaders are gathered in Scotland at a United Nations climate summit, known as COP26, to push nations to ratchet up their efforts to curb climate change. Experts say the amount of energy unleashed by planetary warming would melt much of the planet’s ice, raise global sea levels and greatly increase the likelihood and extreme weather events. Correlating Subsidence Pattern and Land Use Type

Land subsidence is an environmental, geological phenomenon that often refers to gradual settling or rapid sinking of the ground surface as a result of subsurface movement of earth materials. It is considered to be a global issue, and many cities around the world have been reported suffering from land subsidence at the rate of tens of centimeters per year. The impacts of the subsidence could lead to serious issues, for example, damage to infrastructure, affect the serviceability of roads and railways, and increase exposure to flooding.

Radar interferometry, Global Navigation Satellite System (GNSS), close-range photogrammetry (CRP), Robotic Total Stations (RTS), digital levelling, and other modern geodetic measurement techniques have all played an important role in measuring land deformation data. Land deformation data obtained using these techniques has found widespread application in the spatiotemporal analysis of deformation-prone areas. One of the very interesting topics to study is the relationship between land usage type and land subsidence so that land surface change and/or movement can be better understood and managed to ensure people’s safety.

We welcome you to participate in this Research Topic, which will focus on examining the relationship between land usage type and the magnitude of land subsidence. All types of original research contributions will be considered. These include but are not limited to new algorithms, methodologies, and results. Moreover, application papers, including case studies and field measurements, and technical reviews are also welcome.
